

**How Fast Can We Sort?**

**A *decision tree* is a binary tree in which each non-leaf represents a comparison between two elements and each leaf represents a sorted sequence of those elements.**

**Left branch: Yes**

**Right branch: No**

**Example: Apply insertion sort to  $a_1, a_2, a_3$ .**

**A decision tree has one leaf for each permutation of the  $n$  elements to be sorted.**

**The number of permutations of  $n$  distinct elements is ?**

**n!**

**So a decision tree to sort  $n$  elements must have  $n!$  leaves.**

## **The binary-tree theorem:**

**For any non-empty binary tree t:**

$$1. \quad \text{leaves}(t) \leq \frac{n(t) + 1}{2}$$

$$2. \quad \frac{n(t) + 1}{2} \leq 2^{\text{height}(t)}$$

**By the binary tree theorem, for  
any non-empty tree  $t$ ,**

$$\text{leaves}(t) \leq 2^{\text{height}(t)}$$

**Since  $n! = \text{leaves}(t)$ , we must have**

$$\mathbf{n! \leq 2^{\text{height}(t)}}$$

**which implies that**

$$\mathbf{\log_2(n!) \leq \text{height}(t)}$$

**In the context of a decision tree,  $\text{height}(t)$  represents the maximum number of comparisons needed to sort the  $n$  elements.**

**So  $\log_2(n!)$   $\leq$  the maximum number of comparisons to sort  $n$  elements.**

**Therefore,**

**$\text{worstTime}(n) \geq \log_2(n!)$**

$$\log_2(n!) \geq n/2 \log_2(n/2)$$

**So**

$$\text{worstTime}(n) \geq n/2 \log_2(n/2)$$

**So  $\text{worstTime}(n)$  is  $\Omega(n \log n)$  for any comparison-based sort.**

**What can we say about  $\text{averageTime}(n)$ ?**

**averageTime( $n$ )  $\geq$  average number of comparisons  
= total number of comparisons /  $n!$**

**In a decision tree, what is the total number of comparisons equal to?**

**$\text{averageTime}(n) \geq \text{average number of comparisons}$**   
 **$= \text{total number of comparisons} / n!$**

**In a decision tree, what is the total number of comparisons equal to?**

**Hint: The length of each path from the root to a leaf equals the number of comparisons in that path.**

**The total number of comparisons is equal to the sum of all root-to-leaf path lengths.**

**Let  $t$  be a non-empty binary tree.  $E(t)$ , the external path length of  $t$ , is the sum of the depths of all leaves in  $t$ .**

**For example, find the external path length of the following binary tree:**

$$\mathbf{E(t) = 3 + 3 + 3 + 2 + 2 = 13}$$

## **The external path length theorem:**

**Let  $t$  be a binary tree with  $k > 0$  leaves. Then**

$$\mathbf{E(t) \geq (k / 2) \text{ floor } (\log_2 k).}$$

**$E(t)$ , the external path length of tree  $t$ , is the sum of all root-to-leaf path lengths in  $t$ . So the average number of comparisons is**

$$\mathbf{E(t) / n!}$$

**In a decision tree, the number of leaves is  $n!$ .  
so, by the external path length theorem,**

$$\begin{aligned}\text{averageTime}(n) &\geq \text{average \# comparisons} \\ &= E(t) / n! \\ &\geq (n! / 2) \text{ floor } (\log_2(n!)) / n! \\ &= (1 / 2) \text{ floor } (\log_2(n!)) \\ &\geq (1 / 4) (\log_2(n!)) \\ &\geq (n / 8) (\log_2(n / 2))\end{aligned}$$

**For any comparison-based sort,  
averageTime( $n$ ) is  $\Omega(n \log n)$ .**
